Cache invalidation strategies for Internet-based vehicular ad hoc networks

Sunho Lim, Chansu Yu, Chita R. Das

1. Introduction

A vehicular ad hoc network (VANET) consists of a set of high-speed mobile vehicles equipped with communication facilities [1]. It supports inter-vehicle communications through a multi-hop message relay without the assistance of any fixed infrastructure. A variety of applications built for VANETs will be available in the near future as drivers request for more information regarding, for example, safety and traffic conditions. Drivers can monitor/share real-time traffic conditions, exchange files, and send/receive emergency warning messages so that they can pro-actively avoid accidents such as intersection collisions or chained collisions [2,3]. This requires that drivers should be able to access the Internet service and information on wheels [4] through a roadside unit (e.g., an access point (AP), an infostation [5], or a message relay box [6]) located along the road that acts as a gateway to an infrastructure network.

Therefore, in order to provide a flexible connectivity, accessibility, and a rich set of services, it is imperative to consider the integration of a VANET with a wireless infrastructure, such as a wireless local area network (e.g., IEEE 802.11) and a wireless wide area network (e.g., 3G). It is envisaged that such an Internet-based vehicular ad hoc network, or IVANET, will prevail to become an ubiquitous communication infrastructure in the near future.

A key optimization technique in improving the communication performance of IVANETs is to cache the frequently accessed data items in a local storage. In an IVANET, it is less of a problem to determine which data items to cache because the storage space in a vehicle is not critically limited. However, a critical design issue is the cache invalidation scheme, since applications require data consistency with the server to avoid using any stale data. When a data item in a server is updated, it is necessary to invalidate the cached copies of this data item by broadcasting an invalidation report (IR). However, due to fast roaming vehicles, cache invalidation schemes developed for cellular networks and mobile ad hoc networks (MANETS) may not work well. Unlike these conventional networks, energy conservation is not an issue in IVANETS because a vehicle is supported by its own built-in battery. Rather, our concerns are query delay and cache hit ratio in the presence of mobility and frequent data updates.
The following observations characterize the IVANETS in the context of cache invalidation and support our research motivation.

- Due to high-speed mobility, vehicles reside in a coverage area for a short period of time. For example, the connection time within a coverage area ranges from 5 to 24 s at city driving [7]. Therefore, when a data server broadcasts an IR, it is not straightforward which coverage area (s) to target. And, since multiple coverage areas are involved in a broadcast operation, the cost of broadcasting IRs becomes non-negligible.
- Since it is unlikely that adjacent vehicles have common data items in a real IVANET environment, it is wasteful to broadcast the same content of IRs to different vehicles because most of contents may not be relevant to the vehicles.
- It is possible to have a proxy server between a data server and vehicles to reduce the invalidation cost. However, in order to support a scalable invalidation operation, it is essential for a data server or a proxy server to coordinate with location management agents, which increases complexity.

As compared to MANET, the cache invalidation problem in an IVANET is unique because of vehicles’ high-speed mobility and requirement of scalable cache invalidation operation.

To address these issues, we propose and analyze a cooperative cache invalidation (CCI) scheme and its enhancement, called enhanced CCI (ECCI), which can effectively deal with fast moving vehicles without incurring significant overhead. Our contributions are the following:

- First, we suggest a hierarchical network model for IVANETS that consists of access points (APs), gateway foreign agents (GFAs), home agents (HAs), and data server (s). This model facilitates scalable cache invalidation operations as well as efficient location management by having the GFAs to take care of micromobility and micro-invalidations in their respective local areas.
- Second, we propose a cooperative approach, where both a server and location management agents coordinate for cache invalidation. By maintaining a list of data items and the access history by vehicles, a server asynchronously sends an IR to a HA rather than blindly broadcasts to vehicles. Then the HA judiciously refines and distributes the IR to appropriate GFAs, which can answer the validity of the queried data item to reduce the unavoidable query delay, witnessed in most IR-based techniques.
- Third, we develop an analytical model for predicting the performance trends of the proposed two cache invalidation schemes.
- Fourth, we modify two previous cache invalidation schemes, pull-each-read (PER) and extended asynchronous (EAS), to work in IVANETS and compare them against our proposed schemes.

We conduct simulation-based performance evaluation of the four invalidation techniques along with the base case no-cache model to observe the impact of query interval, cache update interval, and data size on system performance, and communication overhead. According to the simulation results, the proposed schemes reduce the query delay up to 69%, increase the cache hit rate up to 57%, and incur lower communication overheads compared to two previous schemes. Overall, our study indicate that the proposed schemes provide better performance at reduced overhead and thus, are a viable approach for adopting IR IVANETS.

The rest of paper is organized as follows. The prior work is reviewed and analyzed in Sections 2 and 3, respectively. The proposed schemes and their analytical models are presented in Sections 4 and 5, respectively. Section 6 is devoted to performance evaluation, comparison, and discussion. Finally, we further exploit several research issues for future directions and conclude the paper in Sections 7 and 8, respectively.

2. Background and related work

Most of cache invalidation schemes deploy one or combination of following design aspects: whether to maintain the cache status or not, who initiates cache validity, and level of cache consistency. First, a server may or may not maintain any cache status. In a stateful approach [8–11], a server keeps track of which mobile node caches which data item. Whenever a data item is updated, the server broadcasts an IR to inform the mobile nodes of the cache update. In a stateless approach [12–14], however, the server is not aware of any cache status and thus, it periodically broadcasts an IR including an update history. Depending on the IR size and broadcast interval, there is a tradeoff between the efficiency of cache invalidation and query latency.

Second, the push/pull/hybrid techniques specify who initiates cache validity. In the push approach [15], the server initiates the cache validity, for example, by broadcasting an IR. In the pull approach [15], however, whenever a query is generated which can be answered from a cached data item, a query request packet is sent to the server to verify the validity of the cached data item before it answers the query. Several push- and pull-based schemes [16] and combining both schemes [17,18] have been proposed considering the tradeoffs between query delay and communication overhead.

Third, depending on a consistency level of cached data items with the server, there could be strong/weak/hybrid consistencies. In the strong consistency [12,14,15], a query is answered by the latest updated data item from either a cache or the server. In the weak consistency [19], however, it needs not reflect the current update of a data item. Thus, it may reduce the communication cost and query delay, but increase the communication overhead due to accessing stale data items. To balance strong and weak consistencies in terms of scalability, complexity, and communication cost, a hybrid cache consistency scheme [17] is proposed, where mobile nodes can flexibly specify their consistency requirements for different types of data items.

In addition, there have been many research efforts on developing various caching schemes for MANETS [18–25] and Internet-based MANETS, called IMANETS [16,17], where MANETS technologies are combined with an Internet to provide a flexible information accessibility and availability for users. For MANETS, Hara and Madria suggested a replication scheme for periodically updated data items based on the previously suggested replica allocation method [20]. Replicated data items are periodically re-allocated depending on the access frequency, remaining time to next update, and network topology. However, estimation of optimal reallocation period and remaining time to the next update are not practically feasible. There are few invalidation approaches [16,17] for IMANETS. In [16], several push and pull-based cache invalidation schemes are proposed based on the aggregate cache [26], in which the aggregated local caches of the nodes can be considered as an unified large cache for the IMANET.

In summary, little effort has been devoted in exploring the cache invalidation issue for IVANETS, where the high-speed mobility and scalability algorithm are primary concerns.

3. Revisit cache invalidation strategies

In this section, we analyze the prior cache invalidation strategies in terms of single- and multi-cell based designs, and formalize the problem in an IVANET environment.

3.1. Single-cell based approach

Most of the prior IR-based schemes are variation of the timestamp (TS) scheme [12], where a base station (BS) broadcasts an
IR every $L$ seconds. Since the IR is periodically broadcasted, there is an unavoidable delay before answering a query. Depending on the length of broadcast interval, $L$, there is a tradeoff between the communication overhead of cache invalidation and query latency. Although an updated invalidation report (UIR) [14] is proposed to further reduce the query latency by adding updated items between IRs, query delay of half of the broadcast interval ($\frac{L}{2}$) still exists. Since the TS scheme does not consider mobility, it cannot be directly deployed in VANETs. For example, when a vehicle generates a query and waits for an IR, it may miss the IR if it has moved to the next adjacent cell. To verify this, we experimented with a single cell environment, where 20 vehicles are randomly located and moved with a given velocity. In Fig. 1(a), as the velocity increases, more vehicles handoff before receiving the IR and thus, the IR miss ratio increases which is sensitive to $L$.

### 3.2. Multi-cell based approach

To reduce the IR miss ratio due to mobility, multi-cell based designs extended from the asynchronous stateful (AS) scheme [8] are proposed, where a network component (e.g. mobile switching center (MSC) or server) located in a higher network hierarchy than a BS executes cache invalidation operations. In [9], when a mobile node handoffs, it either simply drops the cached data items or checks them with the server for validity. Since the server maintains a list of which data items are accessed by which mobile nodes, whenever a data item is updated, it pro-actively unicasts IRs into multiple cells, where the updated data item is cached. In VANETs, however, vehicles stay in a cell for a short period of time and travel along the large number of cells and thus, it is wasteful to examine cached data items with the server for validity upon every handoff. Also, the server’s pro-active IR transmission to multiple cells is neither a scalable solution nor efficient, if the updated data item is not queried.

To verify this, we experiment with a multi-cell environment, where 50 vehicles are randomly located in five cells and move under a wrap around one-dimensional network topology. We compare two schemes extended from [12,9], namely an extended TS (ETS) scheme and an extended AS (EAS) scheme. In ETS, a stateless server broadcasts an IR to every cell in the system whenever vehicles cache an updated data item. In the EAS scheme, however, a stateful server selectively broadcasts an IR to the cell(s). Also, upon handoff, vehicles send all the valid cached data items’ ids to the server for validity and receive an invalidation check packet, which is counted as the IR traffic. In Fig. 1(b), when the cache update interval ($T_u$) is 10 (sec), due to the IR broadcasts to all the cells, the ETS scheme shows the same amount of IR traffics and the impact of velocity on the IR traffic is minimized. When $T_u$ is 100 (sec), the IR traffic reduces. However, the ETS scheme is not scalable in terms of the cache update rate and network size. In the EAS scheme, as the velocity increases, it shows very high IR traffic regardless of cache update interval because of additional invalidation check packets upon every handoff (here, the mean query interval ($T_q$) is set 50 (sec)).

### 3.3. Summary

Although the ETS scheme reduces the impact of mobility, there still exists a non-negligible query delay and the stateless server blindly broadcasts an IR to entire cells in the system, resulting in a scalability issue. On the other hand, the EAS scheme has no query delay when a queried data item is cached and marked as valid, but it incurs heavy IR traffic mainly due to mobility. Thus, reduction of the mobility impact and IR traffic are conflicting requirements, and optimization of both is extremely complex. In light on this, a server is required to keep track of a vehicle’s where abouts under the coordination of other network agents not only to reduce the impact of mobility and IR traffic, but also to provide a scalable solution in VANETs.

### 4. The proposed cache invalidation strategy

In this section, first we briefly introduce a system model and then present our cache invalidation technique.

#### 4.1. System model

As illustrated in Fig. 2, a hierarchical network model for VANET is motivated by a cellular network, and it consists of access points (APs), gateway foreign agents (GFAs), home agents (HAs), and servers of data item source. First, vehicles are equipped with communication facilities such as an IEEE 802.11-based dedicated short range communication (DSRC) transceiver [1]. Thus, they can either communicate with other vehicles or connect to the Internet flexibly. Since providing a location tracking capability in vehicles is becoming popular, we assume that vehicles are aware of their current location. Also, vehicles have a built-in navigation system via GPS, in which a digital map is loaded to show roads around current location and direction, the shortest path to the destination, traffic conditions, location-dependent information, and other information. In addition, unlike cellular and MANET environments,
where nodes move without restrictions, vehicles are bounded to the underlying fixed roads with speed limits and traffic lights in VANETs.

Second, in order to support global wireless access of an Internet, a mobile IP [27] is deployed, in which vehicles are able to access the Internet and maintain their on-going communications, while they move at a high-speed. When a vehicle accesses the Internet, it searches the nearest located AP, which is a gateway to the Internet, to access any information and service. An AP is located in a communication area and can be mounted on the top of a signal light or a road lamp along the road. Also, the AP plays an additional role as a foreign agent (FA). Thus, when a vehicle moves from one coverage area to another, it performs a location update/register operation that involves an AP, a GFA, and an HA. To avoid frequent location register/update operations for fast roaming vehicles, we use an IP micro-mobility support, in which vehicles report the HA only when a major change occurs such as changes to a regional network. In this paper, a 2-way handshake [28] is used to implement location updates by exchanging either a home or regional request/reply packet between a vehicle and a GFA (or HA) through an AP (or GFA).

Third, a database may be attached to any components in the proposed system, e.g., an AP, a GFA, an HA or a database server. However, due to the consistency issue among replicas stored in multiple databases, we assume that the database is attached to a database server. We also assume that the database consists of a total of D data items. A data item (d) is the basic unit of an update or a query operation, where 1 ≤ x ≤ D. The database is only updated by the server, while a query is generated by the vehicles for read-only requests.

4.2. The cooperative approach

In this paper, we propose a cooperative stateful approach, where a server and network agents of location management coordinate together for cache invalidation operations. The server and network agents maintain a list of which data item is accessed by which vehicle and vehicles’ current locations, respectively.Unlike most of the prior stateful designs, the server does not keep track of a vehicle’s current location for IR broadcast. Thus, whenever a data item is updated, it sends an IR to an HA rather than blindly broadcasting the IR to multiple cells, where the updated data item is cached in a vehicle. Then the HA judiciously refines and re-distributes the IR to appropriate GFA (s), where they can answer the validity of a queried data item, requested from a vehicle. Here, GFAs do not pro-actively send the IR to the individual vehicles, but reply a vehicle’s validity request by a on-demand-basis.

The rationale behind this approach is the following: (i) Since a vehicle’s location is implicitly maintained by both a GFA and an HA, the server can avoid keeping track of the vehicles’ current location, which is in fact a duplicated operation with the location management; (ii) Also, since a vehicle has a low probability of finding common data items in adjacent vehicles, broadcasting the same IR to different vehicles is inefficient in VANETS; and (iii) In addition, since the query rate of vehicles is independent of the cache update rate of the server, whenever a data item is updated, a blind IR broadcast incurs heavy IR traffic. The proposed cache invalidation mechanism avoids these issues.

4.3. Proposed cache invalidation technique

In this subsection, we describe the detail operation of the cooperative cache invalidation scheme and its enhanced scheme (ECII). First, a server maintains a list of which data item (dx ∈ D) is accessed by which vehicle in a registry (ri), [id(dx), vid(dx, sx, tdx)], where vi, dx ̸= {vid(dx) ∧ (y ∈ N)}. vid is a vehicle’s id, and tdx is the access time of dx by vi. Here, D and N are the number of data items and vehicles, respectively. Whenever a data item is updated, the server generates an IR (Rv), < id(dx), vid(dx), tdx >, and it is not directly broadcasted to the vehicles but sent to an HA. Here, tdx is the current timestamp. Upon receiving the Rv, since the HA maintains location information about which vehicle is currently roaming under which GFA (gi) in a registry (ri), [vid(dx, sx, y)], it compares the vi with Rv and Rv. Then the HA creates a new IR (Rv), < id(dx), vid(dx), tdx >, based on the matched gi, and sends it to the appropriate GFA. Depending on the number of matched GFAs, more than one Rv can be created. Also, each Rv may have a different size that is less than or equal to the original Rv received from the server. Upon receiving the Rv, the GFA updates its registry and thus, it has the most recent updated IR with the server.

Second, when a vehicle (vi) initially connects to a server, it sends all the ids of cached data items {Gd} and their timestamps, [vid(dx)], to the server, and then the server updates its registry. Here, k = 1 ≤ k ≤ c and c is the total number of cache slots. Whenever the server receives a request packet for validating or accessing a data item, it also updates its registry. Also, when a vehicle hands off to the coverage area which is under a different GFA, then the HA updates its registry and forwards the Rv to the new GFA when a cached data item is updated in the vehicle. The Rv may be forwarded to the appropriate APs to further reduce the query latency, but it is an overhead for the GFA, if a vehicle frequently moves among the coverage areas.

According to the proposed cache invalidation mechanism, let us examine the detail operation of a query request. First, when a vehicle (vi) requests a query for a data item (dx) which is not cached, it sends a request packet for accessing the data item to the server. The packet contains the vehicle’s care-of address (CoA), an id of the requested data item, and a single bit flag (f) representing whether the queried data item is cached or not, [CoA, id(dx), f,], and it is sent to the nearest AP. Here, f is set to 0. As the packet is forwarded to the server through the AP and GFA, CoAs of the AP and GFA are appended in the packet header, [CoA, AP, [CoA, id(dx), f]], to keep the route information. Upon receiving the request packet, the server attaches the queried data item to the ack packet with the route information. The ack packet is replied back to the AP.
via the GFA. Then the AP unicasts the packet and thus, the corresponding vehicle can receive the data item.

**Algorithm 1 Vehicle side**

1. (A) When \(v_p\) generates a query for \(d_k\):  
2. \(f_k = 0\);  
3. if \(d_k \in L_p\) then  
4. \(f_k = 1\);  
5. attach \([f_k, t]_s\) to a request packet;  
6. else  
7. attach \(f_k\) to a request packet;  
8. end if  
9. append \([CoA_{AP}, id(d_k)]\) to the request packet;  
10. send the request packet to the nearest AP;  
11. (B) When \(v_p\) receives an ack packet:  
12. if \(d_k \in L_p\) then  
13. cache \(d_k\) in \(L_p\);  
14. end if  
15. save \(t_s^c\), \(t_{cur}\) in \(L_p\);  
16. answer the query;  

Second, when a query is generated which can be answered by a cached copy of data item, the vehicle sends a request packet to the GFA for checking validity through the nearest AP. The GFA compares the id of queried data item with the \(R_s\) and replies an ack packet, if the cached copy is valid. If the cached copy is not valid, then the GFA forwards the packet to the server. When the server receives the request packet, it verifies the status of the queried data item and replies an ack packet with the route information, if it is a valid copy. If not, it uses the same procedure as the first case to supply the data item. The pseudo codes for the proposed scheme are presented in Algorithms 1–3, where \(L_p\) is a local cache of \(v_p\).

**Algorithm 2 Server side**

1. (A) When a server receives a request packet for \(d_k\) from \(v_p\):  
2. if \(f_k \land [t_s^c \geq t_{cur}^c]\) then  
3. reply an ack packet to \(v_p\);  
4. else  
5. attach \(d_k\) to an ack packet and reply it to \(v_p\);  
6. end if  
7. update \(R_s\), \([id(d_k),\{vid(v_p),t_{s,c}\}]\);  
8. (B) When \(d_k\) is updated:  
9. send an IR, \(<id(d_k),vid(v_p),t_{cur}>\), to an HA;  

Third, to further enhance the CCI scheme, called enhanced CCI (ECCI), the GFAs cache data items in their local storage for future query requests from vehicles. Since an updated data item attached to an ack packet is replied back to vehicles from the server, a GFA intercepts the packet and caches the updated data item. Based on the IR received from the server through HA, GFAs also can maintain a set of valid data items and reply ack packets to vehicles directly, if the queried data item is cached, without forwarding the query request to the server.

In summary, based on the cooperative approach, the server and network agents of the underlying location management coordinate the cache invalidation operations, where the server does not blindly broadcast an IR but sends it to the HA. Then the HA judiciously refines and re-distributes the IR to the GFAs, where the queried data items can be validated or replied.

**Algorithm 3 AP, GFA, or HA side**

1. (A) When an AP receives a request packet from \(v_p\):  
2. append \(CoA_{AP}\) to the request packet and forward it to a GFA;  
3. (B) When a GFA receives a request packet from an AP:  
4. if \(f_k \land [t_s^c \geq t_{cur}^c]\) then  
5. reply an ack packet to \(v_p\);  
6. else  
7. append \(CoA_{GFA}\) to the request packet and forward it to the server;  
8. end if  
9. (C) When an HA receives an IR (\(R_s\)) from the server:  
10. for \(rid(v_p) \in R_s\) do  
11. find a \(CoA_{GFA}\) matched to a \(CoA_{AP}\);  
12. create an IR (\(R_s\)), \(<id(d_k),t_{cur}>\), send it to the GFA;  
13. end for  

5. **Analytical model**

In this section, we analyze the proposed cache invalidation scheme and its enhancement in terms of a cost function. Let \(C_{prot}\) be the average communication protocol cost, which consists of the communication costs of query operation (\(C_{query}\)) and cache invalidation operation (\(C_{invalid}\)):

\[
C_{prot} = C_{query} + \lambda_q \cdot C_{invalid}. \tag{1}
\]

where the arrival process of the query and update is modeled as a Poisson processes with an arrival rate of \(\lambda_q\) and \(\lambda_u\) at a vehicle and a server, respectively. A set of notations used for analysis is summarized in Table 1.

5.1. **The query cost**

Whenever a query is generated, a vehicle accesses the server for validity before answering the query even though the queried data item is cached. Thus, \(C_{query}\) includes the communication cost between a vehicle and an AP (\(C_{v,A}\)), AP and GFA (\(C_{A,G}\)), GFA and the server (\(C_s\)), and the query processing cost at the AP (\(C_{qa}\)), GFA (\(C_{qg}\)), and server (\(C_{qs}\)). We assume that the communication cost is proportional to the distance between a source and destination, and it is represented in terms of the average number of hops (\(h\)) and a constant factor of each hop (\(\kappa\)) [28]. Thus, \(C_{vs}\) and \(C_{qs}\) are \(h \cdot \kappa\) and \(h \cdot \kappa\), respectively. We also assume that the wireless communication cost is \(\omega\) times higher than the wired communication cost and thus, \(C_{qg}\) is \(\omega \cdot \kappa\).

The \(C_{query}\) varies in following three cases: (i) When a queried data item is not cached; (ii) When a cached data item is not valid; or (iii) When a cached data item is valid. Both (i) and (ii) cases are treated as a cache miss, and the query request is forwarded to the server. Then the query cost of cache miss, \(C_{query}^{miss}\), is calculated as:

\[
C_{query}^{miss} = 2 \cdot (q_g + q_q) + q_s + \kappa \cdot (1 + \eta) \cdot \left(h \cdot \kappa + h \cdot \kappa + \omega\right), \tag{2}
\]

where we assume that a data item is transmitted by a number of packets (\(\eta\)) [11]. The third case is a cache hit and the query request is validated in the GFA. Then the query cost of cache hit, \(C_{query}^{hit}\), is calculated as:

\[
C_{query}^{hit} = 2 \cdot q_g + q_q + 2 \cdot \kappa \cdot \left(h \cdot \kappa + \omega\right). \tag{3}
\]

In Eqs. (2) and (3), both \(C_{query}^{miss}\) and \(C_{query}^{hit}\) are represented in terms of the processing and communication costs. By combining Eqs. (2) and (3), \(C_{query}\) is expressed as:
\[ C_{\text{query}} = P_{\text{hit}} \cdot C_{\text{hit}}^{\text{query}} + P_{\text{miss}} \cdot C_{\text{miss}}^{\text{query}}. \]  

where \( P_{\text{hit}} \) and \( P_{\text{miss}} = 1 - P_{\text{hit}} \) are the probability of cached data item being valid and invalid in the GFA, respectively.

The cache hit occurs when a queried data item is cached and accessed before it is updated at the server. Here, let us assume that the number of data items stored in the database is \( D \) and a local cache size is \( \delta \% \) of \( D \). We also assume that the data items are divided into hot (popular) and cold (unpopular) data subsets, and they are \( \% \) and \( \% \) of \( D \), respectively, where \( \% = 100 - \% \). There is a high probability that the data item is chosen in the hot set \( (P_{\text{hit}} < 1) \). Here, \( \% < \% \) and \( P_{\text{cold}} = 1 - P_{\text{hit}} \). Then the probability of the queried data item, which is cached in a vehicle, \( P_{\text{cache}} \), is expressed as:

\[ P_{\text{cache}} = P_{\text{hit}} \cdot \frac{\delta \cdot P_{\text{hot}}}{\%} + (1 - P_{\text{hit}}) \cdot \frac{\delta \cdot (1 - P_{\text{hot}})}{\%}. \]  

If a cached data item is queried after it is updated, then it is an invalid data item. The probability of data item being updated during the period from the current time to the query arrival time is expressed as:

\[ P_{\text{update}} = P(t_q < t_Q) = \int_{t_q}^{t_Q} \int_{t_q}^{t_Q} f(t)g(t)dt_q dt_Q = \frac{\lambda_u}{\lambda_q + \lambda_u}. \]  

where \( t_q \) and \( t_Q \) are the update and query arrival times, respectively. Then we can obtain the hit rate, \( P_{\text{hit}} \), by combining Eqs. (5) and (6) as:

\[ P_{\text{hit}} = P_{\text{cache}} \cdot (1 - P_{\text{update}}). \]  

5.2. The invalidation cost

The \( C_{\text{invalid}} \) includes the communication cost between the server and an HA (\( C_{\text{env}} \)), and the HA and GFA (\( C_{\text{GFA}} \)). Also, the IR update processing costs at server (\( a_i \)), HA (\( a_h \)), and GFA (\( a_g \)) are added as:

\[ C_{\text{invalid}} = a_i + P_{\text{hit}} \cdot \frac{\pi}{\pi} \cdot \kappa \cdot a_h + P_{\text{hit}} \cdot \frac{\pi}{\pi} \cdot \kappa \cdot m + a_g \cdot m, \]  

where \( m \) is the average number of GFAs under an HA, and the communication cost between an HA and the server (\( C_{\text{env}} \)) is similarly derived as \( P_{\text{hit}} \cdot \kappa \).

5.3. Model for the enhancement case

The average communication protocol cost (\( C_{\text{query}}^{\text{enh}} \)) and query cost (\( C_{\text{query}}^{\text{enh}} \)) of the enhancement scheme are the same as Eqs. (1) and (4), respectively except that \( P_{\text{hit}} \) needs to be recalculated. The \( P_{\text{hit}} \) in the GFA, \( P_{\text{hit}}^{\text{GFA}} \), occurs in following two cases: (i) A queried data item is cached in a vehicle and it is validated as a valid copy in the GFA; or (ii) A queried data item is not cached in a vehicle but its valid copy is cached in the GFA.

The first case is the same as the Eq. (7). In the second case, the probability of the queried data item, which is cached in the GFA, \( P_{\text{cache}}^{\text{enh}} \) needs to be calculated and it is expressed as:

\[ P_{\text{cache}}^{\text{enh}} = P_{\text{hit}} \cdot \frac{\gamma}{\%} + (1 - P_{\text{hit}}) \cdot \frac{\gamma \cdot (1 - P_{\text{hit}})}{\%}. \]  

where we assume that the cache size of a GFA is \( \% \% \) of \( D \). Here, \( \% < \% \).

Then \( P_{\text{hit}}^{\text{enh}} \) is given by,

\[ \left\{ \begin{array}{ll}
P_{\text{cache}} \cdot (1 - P_{\text{update}}) & \text{(i) case} \\
(1 - P_{\text{cache}}) \cdot P_{\text{cache}}^{\text{enh}} \cdot (1 - P_{\text{update}}) & \text{(ii) case}
\end{array} \right. \]  

By combining both the cases, \( P_{\text{hit}}^{\text{enh}} \) is expressed as:

\[ C_{\text{query}}^{\text{enh}} = P_{\text{hit}} \cdot C_{\text{hit}}^{\text{query}} + \left( P_{\text{hit}}^{\text{GFA}} - P_{\text{hit}} \right) \cdot C_{\text{hit}}^{\text{query}} + P_{\text{hit}}^{\text{GFA}} \cdot C_{\text{miss}}^{\text{query}}. \]  

Compared to Eq. (4), additional processing and communication costs (\( C_{\text{query}}^{\text{enh}} \)) between a vehicle and GFA are added in Eq. (11). This is because when a queried data item is not cached in the vehicle but cached in the GFA, it should be delivered to the vehicle in the enhancement scheme. Thus, \( C_{\text{query}}^{\text{enh}} \) includes the costs for validating a query request in the GFA and delivering a queried data item from the server or GFA to the vehicle.

We show the numerical results of both the average communication protocol cost and cache hit in Fig. 3. The query processing costs at the AP, GFA, and server are set to 10, 15, and 25, respectively. Similarly the update processing costs at the GFA, HA, and the server are set to 10, 15, and 25, respectively. The local cache sizes in a vehicle and a GFA are set to 5% of database, respectively. In Fig. 3(a), both communication protocol costs increase as both query and update rates increase, but they are more sensitive to the update rate. In Fig. 3(b), the cache hit increases as the query rate increases but it decreases as the update rate increases. The enhancement case achieves better performance because of additional caching in GFAs, that helping consuming more query requests directly without forwarding them to the server.

Since the proposed model is intended only to estimate the performance trend, we conduct detail performance evaluation through extensive simulation in the following section. The performance optimization could improve the usefulness of the analysis but it is beyond the scope of this paper. For example, the query cost can be reduced by caching more valid data items at GFAs. However, the invalidation cost may increase due to frequent validation operations between the server and GFAs. Thus, reduction of the query and
invalidation costs is conflicting requirements, and optimization of both is admittedly extremely complex.

6. Performance evaluation

6.1. Simulation testbed

We develop a customized discrete-event simulator using CSIM19 [29] to conduct our experiments. To examine the proposed idea, we use a simple wrap around one-dimensional network topology (see Fig. 4) with a velocity suitable for a city driving under emphasis on the data caching and its invalidation. In this paper, we neither consider a high speed mobility model nor deploy an advanced location management scheme (i.e., [28]) to clearly see the effect of our cache invalidation strategies on the performance.

We deploy 25 APs\(^1\) to cover the area and assume that each AP is located in the center of a coverage area with 2 Mbps bandwidth. Five GFAs are deployed in the area and each GFA consists of 5 APs. A set of vehicles is randomly located in the area, travels with a given velocity suitable for a city driving, and communicates with the APs. The communication delay is dependent on the distance among wired network agents (e.g., AP, GFA, HA, and server) represented by the number of hops. Based on [28], the number of hops between an AP and a GFA, a GFA and HA, a GFA and the server, and the server and HA are set to 5, 10, 25, and 25, respectively. We assume that the bandwidth of the wired network is 100 Mbps.

Both update and query inter arrival times follow the exponential distribution. The entire data items stored in the database is classified into two subsets, hot and cold data items. We assume that 80% and 20% of update requests are uniformly distributed within the hot and cold subsets, respectively. The Zipf distribution model [32] is often used to model a skewed access pattern, where \( \phi \) is the access skewness coefficient. The access probability of the \( i \)th data item is represented as \( \frac{1}{\phi} \), where \( \phi = \left( \sum_{i=1}^{n} \frac{1}{i} \right)^{-1} \), and \( 0 \leq \phi \leq 1 \). Setting \( \phi = 0 \) corresponds to the uniform distribution. Here, we set \( \phi \) to 0.8 based on the real Web traces [33].

Each vehicle caches 5% of the data items in the database. When a cache is full, we use the least recently used (LRU) cache replacement policy. We do not deploy an advanced cache admission or replacement policy proposed in [26] to clearly see the effect of the proposed scheme on the performance. The simulation parameters are summarized in Table 2.

6.2. Performance comparison

To compare the performance of proposed schemes, we modified two prior cache invalidation techniques to work in IVANET: a poll-each-read (PER) scheme, and an extended asynchronous (EAS) scheme. The PER\(^2\) scheme [10] is an on-demand approach extended from [34], where a query is forwarded to the server for either validating a cached data item or receiving the queried data item. In

---

\( ^1 \) The AP (e.g., an infostation [30,5], or a message relay box [6]) to cover the area, and they are located along the road and act as a gateway to an infrastructure network. We envision that drivers should be able to access not only roadside Wi-Fi stations but also high-speed wide area 3G cellular networks and thus, the diameter of coverage area will become wider than that of we have assumed based on [31] in this paper.

\( ^2 \) A server-based poll-each-read (SB-PER) scheme [10] is proposed to further improve the performance of PER under the assumption of available global access and update information in a server. However, obtaining the global update information is practically infeasible and thus, we do not consider the SB-PER scheme in this paper.
the EAS\(^3\) scheme, as we mentioned in Section 3, a stateful server maintains a list of ids of the cached data items in vehicles, and broadcasts an IR to inform the vehicles of any cache update. Thus, a queried data item, which is cached, is used to answer the query directly without validating with the server. When a vehicle handoffs, it sends the entire valid cached data item ids to the server for validity check and receives an invalidation check packet from the server. For comparison, we add the proposed cooperative approach in these schemes, where the impact of mobility on the performance is minimized. In addition, we include the base case, no cache (NC), where a query request is forwarded to the server always.

6.3. Simulation results

We evaluate the impact of update interval \((T_u)\), query interval \((T_q)\), and size of data items, and examine the communication overheads of the cache invalidation strategies.

6.3.1. Impact of update interval

First, we evaluate the query delay and cache hit rate of cache invalidation strategies as a function of update interval. In Fig. 5(a), as the update interval increases, the query delay decreases. The NC scheme is not affected by the update and query intervals because every query is forwarded to the server for access. In Fig. 5(b), when the query interval is high, the overall query delays increase because more cached data items become invalid before they are queried. Both PER and EAS schemes show high query delays closer to the NC scheme in the low update intervals, but the EAS scheme exhibits lower query delay with high update intervals, because more valid cached data items are found without additional validation delay with the server. Both our CCI and ECCI schemes show better performance than other two schemes. Especially the ECCI scheme shows the lowest query delay for the entire update intervals due to additional caching in the GFAs.

In Fig. 6(a), as the update interval increases, the cache hit rate increases. Both CCI and ECCI schemes show higher cache hit rates than other two schemes because a query can be validated or answered in the GFA before it is forwarded to the server. The detail analysis of cache hit is presented in Fig. 9(a) later. In Fig. 6(b), when the query interval is high, the overall cache hits decrease. However, the ECCI scheme is not affected much by both query and update intervals and shows the highest cache hit rate for the entire update intervals.

6.3.2. Impact of query interval

Second, we examine the query delay and cache hit of the cache invalidation strategies as a function of query interval. In Fig. 7(a), when the update interval is low, both PER and EAS schemes show almost similar performance to the NC scheme except for the low query intervals. This is because, due to frequent update of data

---

\(^3\) Both asynchronous (AS) [9] and call-back (CB) [35] schemes are similar in the sense that a stateful server broadcasts an IR to the mobile nodes for cache updates. Since the CB scheme is designed for a single-cell environment, we extend the AS scheme for comparison in this paper.
6.3.3. Impact of cooperative approach

Third, we analyze the proposed schemes in terms of the local cache hit and a remote cache hit. The local cache hit is the ratio that a queried data item is locally cached and validated by the server, while the remote cache hit is the ratio that a queried data item is validated or found from the GFAs. In the ECCI scheme, the remote cache hit can be enhanced when a queried data item is cached in GFAs. In Fig. 9(a), when the pair of query and update interval is 10/100 (sec), both CCI and ECCI schemes show higher cache hits than other two schemes. The CCI scheme achieves the highest remote cache hit because many queries are validated in the GFAs before they are forwarded to the server. However, the ECCI scheme shows higher local cache hit than other three schemes because many queried data items found in the GFA brought to the query request senders for caching. Then these cached data items are used for answering the next query requests, resulting better local cache hits. In case of 100/10 (sec), due to frequent update of data items, both PER and EAS schemes show no cache hit, while both CCI and ECCI schemes heavily rely on the remote cache hit.

6.3.4. Impact of data size

Next, we measured the query delay as a function of data size. In Fig. 9(b), the ECCI scheme outperforms the others and achieves the lowest query delay for all data sizes. The performance gap between the NC and other schemes is larger as the data size increases. Due to additional communication with the server on every query request for validating or accessing the data items, both NC and PER schemes show higher query delays than the other three schemes.

6.3.5. Communication overhead

Finally, we evaluate the communication overhead of the cache invalidation strategies in terms of the average number of packet transmissions only from the network components including the query request, reply, and IR packet transmissions. In Fig. 10, both NC and PER schemes require six packet transmissions from a vehicle, AP, GFA, and server for answering a query. Although additional IR transmission from the server and HA is required in both CCI and ECCI schemes, they achieve the less number of packet transmissions than
In summary, the proposed cooperative cache invalidation schemes provide better performance and less overhead. The cooperative approach reduces the impact of high-speed mobility and provides a scalable cache invalidation operation, because a server and network agents of location management coordinate together for cache invalidation operation. Thus, the proposed schemes are a viable approach for implementing iVANETS.

6.4. Discussion

In this subsection, we discuss how the simulation parameters and assumptions affect the caching performance. We first investigate how data access pattern affects the caching performance. In this paper, a skewed access pattern is considered and the Zipf distribution model [32] is deployed based on the real Web traces (i.e., \( \theta = 0.8 \)). Since frequently accessed data items (i.e., hot data items) are highly preferred to be cached, a non-uniform data access pattern is implicitly assumed in most caching schemes. If the data access pattern is uniform (i.e., \( \theta = 0.0 \)), the benefits of caching in terms of low query delay and communication overhead reduce. Also, the problem of data caching can be turned into data replication [20,36], where multiple copies of data item are stored in local caches and a performance tradeoff between data accessibility and access latency is a major performance matrix.

Second, we investigate how packet collision or loss affects the caching performance. In this paper, no packet (i.e., IR) collision or loss is assumed between vehicles and APs. We can relax this assumption by considering limited broadcast bandwidth, unreliable wireless link, or high vehicle density often witnessed in a rush hour or a city event. In case of IR packet collision or loss, the query delay increases because a vehicle cannot answer a query until it receives the IR. Due to lack of receiving IRs, long-disconnection problem [13] can be occurred and the entire cached data items can be thrown away for validation. Thus, overall caching performance will decrease.

7. Research issues

We further exploit several issues open for investigation toward future research directions. First, we envision that vehicles will be able to access not only roadside Wi-Fi stations but also 3G networks. Here, in contrast to 3G networks, roadside Wi-Fi stations have advantage of easy to deploy with low cost but provide high bandwidth. When each vehicle has a connection supported either by 3G networks or satellite techniques, its high-speed mobility still becomes an issue for cache invalidation operation. In light of this, coordination with location management scheme is essential to reduce the cost of IR broadcast. Since vehicles are bounded to move under a fixed road with speed limits and traffic lights, prediction of future movement considering such restrictions will also reduce the impact of mobility.

Second, as compared to MANETS and VANETS, the unique challenges in iVANETS such as scheduling [37] and data dissemination [38] will motivate further research in this area. Since vehicles moves with high-speed, they have a short period of time to contact a roadside unit for download and upload requests. As the number of vehicles increases in a rush hour, it is not trivial to design an efficient scheduling scheme for the server to process the requests in a timely manner. Due to vehicles’ high-speed mobility, the conventional broadcast technique for data dissemination cannot directly be applied to MANETS. In iVANETS, the roadside unit (e.g., data source) broadcasts data items to passing by vehicles and they exchange the data items with other vehicles located within the communication range. Also the roadside unit periodically broadcasts data items at the intersection, and vehicles can buffer and re-broadcast the data items at the intersection for easy of data dissemination. These
techniques can improve the data accessibility and availability and reduce the network traffic.

Third, in this paper, we implicitly assume a strong consistency model, in which a query should be answered by the latest updated data item from either a local cache or the server. However, we need to relax this assumption to support growing diversity in applications and users’ demands requiring a certain consistency level with the server. Note that ensuring a strong consistency is not always a prompt and critical requirement. For example, map, video clip, and weather information are not update sensitive and thus, occasional inconsistency between the source and its cached copy would be acceptable. Little effort has been devoted in developing a flexible consistency-based technique [17,39]. We expect that this technique can effectively balance among the cost of accessing data item, complexity of consistency maintenance, and query latency.

8. Conclusion

In this paper, we investigate the cache invalidation issue in an IVANET, where minimizing the impact of high-speed mobility and designing a scalable algorithm are primary concerns. We proposed a hierarchical network model and a cooperative cache invalidation scheme including its enhancement, in which both the server and network agents of location management coordinate the cache invalidation operation. We developed a simple analytical model for the proposed schemes for rapid estimate of performance trends. We also compared the proposed schemes with two prior cache invalidation schemes through extensive simulation, and observed that the proposed CCI and ECCI schemes provide better performance than others with respect to the query delay, cache hit rate, and communication overhead.
