To further elucidate the nature of the valence state of V ions in vanadate glasses, magnetic susceptibility measurements in the temperature range of 5 to 300 K have been performed on a series of vanadium–strontium–borate (V₂O₅ + SrO + B₂O₃) oxide glasses with V₂O₅ concentrations greater than 50 mol %. The magnetic susceptibility for these oxide glasses is found to consist of a temperature-independent paramagnetic contribution arising from V₂O₅ and a Curie–Weiss temperature-dependent contribution associated with magnetic V⁴⁺ ions being present in concentrations between 2% and 10% of the total V concentration. The negative Curie–Weiss temperatures in the range of 0 to −2.8 K indicate a weak antiferromagnetic interaction between the V⁴⁺ ions. These results are consistent with a glass network structure consisting of VO₅ polyhedra in which the V⁴⁺ would be predominantly isolated species, and any interactions between the V⁴⁺ ions would result from superexchange interactions through V–O–V bonds. © 2002 American Institute of Physics. I. INTRODUCTION

Studies on oxide glasses containing transition-metal (TM) ions continue to be of interest due to their semiconducting properties that arise from the hopping of unpaired electron(s) between TM ions having two different valence states. Since vanadium can exist in several different oxidation states (e.g., V⁵⁺ and V⁴⁺), these vanadate glasses can exhibit electrical (semiconducting) and magnetic (superparamagnetic) properties that are of particular technological importance. The present work extends previous studies on the magnetic properties of vanadate glasses by investigating the magnetic properties on a series of V₂O₅–SrO–B₂O₃ glass samples. Magnetic susceptibility (χ) measurements in combination with inductively coupled plasma spectroscopy (ICP) have been used to determine the ratio of different valence states of the V ions in these glasses. In addition, the possibility exists for magnetic interactions between the conjugate ions V⁴⁺ (3d¹). The extent and nature of this interaction can correspondingly be deduced from parameters associated with the observed Curie–Weiss behavior [χ = C/(T−θ)] of these glasses.

II. EXPERIMENT

A. Glass preparation

The glasses were prepared by melting dry mixtures of reagent grade V₂O₅, SrO, and B₂O₃ in alumina crucibles with various batch compositions as shown in Table I. Approximately 30 g of chemicals were thoroughly mixed to obtain homogenized batches. The crucible containing the batch mixture was placed in a furnace, heated at 300 °C for 1 h and then transferred to an electrically heated melting furnace maintained at 1100 °C. The melt was left for about 3.5 h under atmospheric conditions in the furnace during which the melt was occasionally stirred with an alumina rod. The homogenized melt was then cast onto a stainless steel plate mold to form glass buttons from which smaller pieces were cut for magnetic measurements. The actual compositions of the glasses were determined by ICP and are listed in Table I.

B. Magnetization measurements

The temperature-dependent dc magnetic susceptibility was measured using a Quantum Design SQUID magnetometer (model MPMS-5S) in a magnetic field of 5000 Oe over a temperature range of 5 to 300 K. The susceptibility of the sample holder is negligible below 100 K for all samples, with less than a 2% correction at the highest temperature for all samples. The overall accuracy of the magnetic measurements is estimated to be approximately 3% due to the uncertainty of the magnetometer calibration.

III. RESULTS AND DISCUSSION

The magnetic susceptibility results for a series of (V₂O₅)ₓ(SrO)₁₋ₓ glass samples where x = 0.8, 0.7, and 0.6 are displayed in Fig. 1 as plots of the inverse magnetic susceptibility, 1/χ, as a function of the temperature, T. The susceptibility data do not appear to follow a simple Curie–Weiss behavior [M/H = C/(T−θ)] as there is a distinct downward curvation in the data over the entire temperature range. After attempting several other fitting possibilities, it was found that the data for each sample could be fitted to a positive temperature-independent constant plus the Curie–
Weiss temperature-dependent term. The temperature-independent constants are determined from a high-temperature extrapolation of $M/H$-versus-$1/T$ plots for temperatures above 200 K. After subtracting these temperature-independent constants from the measured susceptibility data, the resulting $M/\chi_{\text{param}} = M/H - (M/H)_{\text{const}}$ data follow a Curie–Weiss behavior as demonstrated in Fig. 2. The magnetic susceptibility data for the other two series of glasses, $(V_2O_5)_{x}(SrO)_{0.2} (B_2O_3)_{0.8}$, also show a similar behavior and were fitted to a temperature-independent term plus the temperature-dependent Curie–Weiss contribution following an analogous procedure. The temperature dependence of the resulting inverse susceptibility, $\chi^{-1}$, after subtracting out the temperature-independent constants for the other two series of vanadate glasses are shown in Figs. 3 and 4. The resulting parameters—$(M/H)_{\text{const}}$, the Curie constant $C$, and the paramagnetic Curie temperature $\theta$—obtained from this fitting procedure are listed in Table I for all samples. Note that the magnitude of the temperature-independent term, $(M/H)_{\text{const}}$, is about one order of magnitude smaller than the Curie–Weiss contribution at room temperature.

A temperature-independent contribution can be expected to be present in these oxide glasses as the V$^{2+}$, V$^{4+}$, Sr$^{2+}$, B$^{3+}$, and O$^{2-}$ ions will give rise to a temperature-independent diamagnetic contribution, while V$_2$O$_5$ gives a temperature-independent paramagnetic contribution on the order of $10^{-4}$ emu/mol Oe. Since this latter value is an order of magnitude larger than the typical diamagnetic contributions from the core ions, we can expect that the V$_2$O$_5$ paramagnetic contribution will dominate over the response arising from the core diamagnetism of the glass ions. This is in agreement with the experimental evidence of $(M/H)_{\text{const}}$ being positive. Furthermore, this interpretation is consistent with the V$_2$O$_5$ concentration dependence of $(M/H)_{\text{const}}$ for the entire series of glasses. For example, $(M/H)_{\text{const}}$ for the $(V_2O_5)_{x}(SrO)_{1-x}$ glasses increases as $x$ increases while there is less variation in $(M/H)_{\text{const}}$ for the $(V_2O_5)_{x}(SrO)_{0.5}(B_2O_3)_{0.5}$ glass series having a fixed vanadium concentration.

Since V$^{5+}$ ions are nonmagnetic, the Curie–Weiss behavior observed in these glasses must be associated with a fraction of the vanadium ions being in another oxidation state, most probably V$^{4+}$. X-ray photoemission spectroscopy studies on identical glass samples support this hypothesis as the V $2p$ spectra show two peaks, one associated with the presence of V$^{5+}$ ions and a smaller one associated with V$^{4+}$. Thus, determinations of the Curie–Weiss parameters in con-

junction with concentration determinations by chemical analysis on these oxide glasses result in magnetic V$^{4+}$ ions ($p_{\text{eff}} = 1.73 \, \mu_B$) being present in concentrations between 2% and 10% of the total V concentration for these glasses. These percentages are consistent with other recent results$^8$ on strontium vanadate glasses as well as the trend for increasing V$^{4+}$ concentrations with increasing V$_2$O$_5$ concentrations. As a result, one would expect the electrical conductivity to be the highest for the glasses having the largest V$_2$O$_5$ concentrations as the availability of unpaired 3$d^1$ electrons to hop from the V$^{4+}$ sites to the V$^{5+}$ sites would be greater.

The $\theta$ values found in the present measurements of these vanadate glasses are found to range from 0 to $-2.8 \, \text{K}$, indicating a weak antiferromagnetic interaction between the V$^{4+}$ ions. Typically the values of $\theta$ are proportional to the strength of the interaction and the number of neighboring magnetic ions. Assuming a glass network structure consisting of mainly VO$_5$ polyhedra,$^8$ any interactions between the V$^{4+}$ ions result from superexchange interactions through V–O–V bonds. Owing to the low content of V$^{4+}$ ions in these vanadate glasses, V$^{4+}$ would exist predominantly as isolated species in these concentrated vanadate glasses with a limited number of V$^{4+}$–O–V$^{4+}$ bonds being present.

In conclusion, magnetic susceptibility measurements in the temperature range of 5 to 300 K have been performed on a series of strontium–borate–vanadate (V$_2$O$_5$ x SrO y B$_2$O$_3$) glasses to elucidate the nature of the valence state of the V ions. The magnetic susceptibility was found to consist of a temperature-independent paramagnetic contribution arising from V$_2$O$_5$ and a Curie–Weiss temperature-dependent contribution associated with magnetic V$^{4+}$ ions being present in concentrations between 2% and 10% of the total V concentration. The negative Curie–Weiss temperature values in the range of 0 to $-2.8 \, \text{K}$ indicated a weak antiferromagnetic interaction between the V$^{4+}$ ions.
