Thermodynamic characterization of five key kinetic parameters that define neuronal nitric oxide synthase catalysis

Mohammad Mahfuzul Haque , Jesús Tejero , Mekki Bayachou , Zhi-Qiang Wang Mohammed Fadlalla and Dennis J. Stuehr

NO synthase (NOS) enzymes convert L-arginine to NO in two sequential reactions whose rates (k_{cat1} and k_{cat2}) are both limited by the rate of ferric heme reduction (k_r). An enzyme ferric heme NO complex forms as an immediate product complex and then undergoes either dissociation (at a rate that we denote as k_d) to release NO in a productive manner, or reduction (k_r) to form a ferrous heme NO complex that must react with O_2 (at a rate that we denote as k_{ox}) in a NO dioxygenase reaction that regenerates the ferric enzyme. The interplay of these five kinetic parameters (k_{cat1}, k_{cat2}, k_r, k_d and k_{ox}) determines NOS specific activity, O_2 concentration response, and pulsatile versus steady-state NO generation. In the present study, we utilized stopped-flow spectroscopy and single catalytic turnover methods to characterize the individual temperature dependencies of the five kinetic parameters of rat neuronal NOS. We then incorporated the measured kinetic values into computer simulations of the neuronal NOS reaction using a global kinetic model to comprehensively model its temperature-dependent catalytic behaviours. The results obtained provide new mechanistic insights and also reveal that the different temperature dependencies of the five kinetic parameters significantly alter neuronal NOS catalytic behaviours and NO release efficiency as a function of temperature.

Introduction

Nitric oxide (NO) is a biological mediator produced in animals by three NO synthase isozymes (NOS; EC 1.14.13.39): inducible NOS (iNOS), neuronal NOS (nNOS) and endothelial NOS (eNOS) [1,2]. NOS enzymes catalyze a stepwise oxidation of L-arginine (Arg) to form nitric oxide and citrulline [3 5]. In the first reaction, Arg is hydroxylated to form N^ω-hydroxy-L-arginine (NOHA) and, in the second reaction, the NOHA intermediate is oxidized to form NO and citrulline (Scheme 1) [1]. Both steps consume one molecule of O_2 and utilize NADPH-derived reducing equivalents. NOS proteins comprise an N-terminal oxygenase domain and a C-terminal flavoprotein domain, with a calmodulin (CaM)-binding site connecting the two domains [6], and each NOS is only active as a homodimer [6,7]. The oxygenase domain binds Fe protoporphyrin IX (heme), the substrate Arg and the essential cofactor (6R)-tetrahydrobiopterin (H_4B) [8,9], whereas the flavoprotein domain binds FAD, FMN and NADPH [10 12]. During catalysis, the flavoprotein domain provides electrons to the heme in the NOS

oxygenase domain, which enables the heme to bind O_2 and initiate oxygen activation in both reactions of NO synthesis [13 15]. Heme reduction also requires that CaM be bound to NOS, and is rate-limiting for the NO biosynthetic steps.

NOS enzymes operate under the constraint of being heme proteins that generate NO, a good heme-binding ligand. Indeed, their newly-made NO binds to the ferric heme many times before it can exit the enzyme [16]. How this intrinsic heme-NO-binding event impacts NOS catalytic cycling is shown in Fig. 1 and has been discussed in detail previously [16 20]. The Arg to NO biosynthetic reactions [Fe^{III} to ferric heme NO complex ($Fe^{III}NO$) steps in Fig. 1] involve two sequential oxidation reactions whose rates are both limited by the rate of ferric heme reduction (k_r) because all subsequent catalytic steps in either reaction (termed k_{cat1} and k_{cat2} in Fig. 1) occur faster than k_r. Once the $Fe^{III}NO$ product complex forms in NOS, it can either dissociate and enable the release of NO into the medium (at a rate k_d as shown in Fig. 1) or
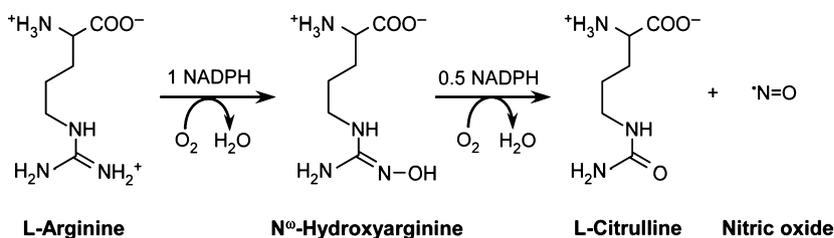

**Scheme 1.** Biosynthesis of nitric oxide from L arginine.

Fig. 1. Global kinetic model for NOS catalysis. NOS enzymes start with their heme in the ferric state (left side, yellow Fe^{III}). The FMN to heme electron transfers (ETs) (designated k_r) allow O_2 to bind to heme to start catalysis, and are rate limiting for the two sequential oxidation reactions (horizontal line). k_{cat1} and k_{cat2} are the conversion rates of the enzyme $Fe^{II}O_2$ species (green) to products in the L Arg and N^ω hydroxy L arginine (NOHA) oxidation reactions, respectively. A $Fe^{III}NO$ product complex ($Fe^{III}NO$, blue) can either release NO (k_d) or become reduced (k_r') to a $Fe^{II}NO$ complex ($Fe^{II}NO$, red), which reacts with O_2 (k_{ox}) to regenerate ferric enzyme through a futile cycle that destroys the NO. The five kinetic parameters and reactions that we studied are indicated by the red boxes.

become reduced by the flavoprotein domain (at a rate k_r' in Fig. 1; assumed to be equal to k_r) [21] to form the enzyme ferrous heme NO species ($Fe^{II}NO$), which releases NO extremely slowly [18,19]. Consequently, the $Fe^{II}NO$ species must undergo reaction with O_2 at a rate k_{ox} (Fig. 1) to regenerate the ferric enzyme and return to an active form. Thus, two cycles exist during steady state NO synthesis (Fig. 1): NO dissociation from the enzyme (k_d) is part of a 'productive cycle' that is essential for NOS bioactivity, whereas reduction of the $Fe^{III}NO$ product complex (k_r') channels NOS into a 'futile cycle' that actually represents a NO dioxygenase activity. The rate constants for each step of NOS catalysis are shown in Fig. S1.

Observed rates for k_r, k_{cat}, k_d and k_{ox} have been measured in NOS enzymes in single catalytic turnover reactions [14,18,19,22 25]. However, because most of the measures have been obtained at only a single temperature (10 °C, or less often at 25 °C), little or nothing is understood regarding the temperature dependencies and thermodynamic properties of the individual steps, as well as how they combine to govern the catalytic behaviour and overall activities of NOS enzymes. This information would improve our understanding NOS catalysis and enable the accurate modelling of its catalytic cycle under physiological temperatures and conditions. In the present study, we poised rat nNOS at different points in the cycle, and utilized stopped-flow spectroscopy to characterize the temperature dependence of five individual kinetic parameters (k_r, k_{cat1}, k_{cat2}, k_d and k_{ox}). The thermodynamic parameters of these individual reactions provide new insights regarding NOS structure reactivity relationships and provide a better understanding of their physiological relevance.

Results and Discussion

Temperature dependence of heme reduction (k_r)

We directly assessed electron transfer (ET) from FMN hydroquinone to heme using stopped-flow spectroscopy under anaerobic conditions. Heme reduction was monitored via the formation of the $Fe^{II}CO$ complex at 444 nm. Once ferrous heme is formed by ET from the FMN, the fast and stable binding of CO prevents the accumulation of the ferrous species and makes the ET reaction essentially irreversible. This mimics the normal condition of having O_2 present to react with ferrous heme, and insures that the observed rate of heme reduction does not have a significant back reaction component. The reactions were initiated by mixing CaM-bound nNOS with excess NADPH [26], and heme reduction rates (k_r) were measured at 5, 10, 15, 20, 25, 30 and 37 °C. Representative diode array spectra (Fig. 2, upper panel) and the resulting kinetic trace (Fig. 2, upper panel inset) are shown. We fit the kinetic traces to a bi-exponential function, with the initial fast phase representing an absorbance decrease as a result of flavin reduction by NADPH, and the subsequent slower phase representing the absorbance increase as a result of heme reduction in the presence of CO. The observed rates obtained for heme reduction at each temperature are provided in Table 1. The heme reduction rate increased approximately 1.5-fold with every 10 °C rise in temperature. Fitting the experimental data to the linearized form of the Arrhenius equation yielded an activation energy of E_a = 31.5 kJ·mol^{-1}. A linear Eyring plot (Fig. 2, middle panel) of the data yielded values for the enthalpy and entropy of activation for the heme reduction step: $\Delta H^{\ddagger}$ = +29.1 kJ·mol^{-1}; $\Delta S^{\ddagger}$ = −128 J·mol^{-1}·K^{-1} (Table 2). The derived Gibbs free energy of activation $\Delta G^{\ddagger}$ at 25 °C was calculated as 67.2 kJ·mol^{-1}. The $\Delta G^{\ddagger}$ increases with temperature, which is expected, given the negative entropic contribution. The activation enthalpy and entropy values for heme reduction that we determined for nNOS are similar to values recently reported for human iNOS (36.9 kJ·mol^{-1} and −89.7 J·mol^{-1}·K^{-1}, respectively), which were derived using a different measurement method (flash photolysis) [27]. This suggests that similar mechanisms may govern heme reduction among NOS isozymes.

interprotein ET reactions, such as in cytochrome *c*-plastocyanin [32 34], indicate modest enthalpies and high negative entropies, similar to the values that we found for nNOS with respect to its putative interdomain FMN-to-heme ET. The high negative activation entropy determined for nNOS suggests that the rate-limiting elementary step of the heme reduction process is characterized by a relatively ordered transition state.

Because heme reduction in nNOS involves an ET reaction between the FMN and heme prosthetic groups, we analyzed the temperature dependence data of heme reduction in the framework of the semiclassical Marcus theory describing nonadiabatic ET reactions [35]. This approach has been successfully applied to several biological ET systems to shed light on quantitative aspects of the ET step [36,37]. It is important to note that heme reduction in NOS enzymes is a relatively complex multistep process. A protein conformational change that involves both long- and short-range motions is expected to bring the FMN domain into close proximity to the heme centre in the oxygenase domain of the nitric oxide synthase (NOSoxy) [38,39]. Mutational and kinetic studies suggest that the FMN domain first undergoes a long

Fig. 2. Temperature dependence of ferric heme reduction (k_r) in nNOS. Anaerobic ferric nNOS (~ 10 μM) was mixed at various temperatures with NADPH (100 μM) in CO saturated buffer in the stopped flow apparatus and build up of the Fe^{II}CO absorbance peak (444 nm) was used to measure the rate of heme reduction. Upper panel: rapid scanning spectra recorded during a representative reaction run at 10 °C and the accompanying kinetics of spectral change (inset). Middle panel: Eyring plot of the measured heme reduction rates, with slope $\Delta H^{\ddagger}$/R and the intercept $\Delta S^{\ddagger}$/R + ln (k_B/h). Lower panel: temperature dependence of the nNOS heme reduction rate in the context of the Marcus ET theory. The solid line represents a nonlinear least squares fit of the data using Equation (1) as described in the text. The derived Marcus parameters (λ and H_{DA}) giving the best fit are shown.

range motion to swing away from the ferredoxin NADP-reductase (FNR) domain and then undergoes short-range sampling motions to productively dock on the NOSoxy domain, which is in part guided by complementary charged residues on the domain domain interface [11,39 41]. These conformational change(s) precede the actual ET and could conceivably influence the kinetics and thermodynamic behaviour of the heme reduction that we observe. The ET process would be gated if the conformational change is rate-limiting, whereas, if the actual FMN-to-heme ET step is rate-limiting, the process could be either true-ET or coupled-ET. In true-ET, the ET step is rate-limiting and not kinetically influenced by preceding steps, whereas, in coupled-ET, the ET reaction is still rate-limiting but is preceded by a relatively fast and thermodynamically unfavourable non-ET reaction such as conformational change. Although the FMN to heme ET in NOS enzymes has been reported to be conformationally-gated [42], a detailed study on this aspect is lacking. Application of the Marcus ET formalism to our temperature dependence data provides an opportunity to quantify parameters such as the required reorganization energy, as well as electronic coupling between the FMN electron donor and heme electron acceptor during ET. The rate constant for nonadiabatic ET, k_{ET}, is generally described by Equations (1,2) which respectively, derive from the prediction that rates of ET exhibit Gaussian free-energy dependence, and from the fact that electronic coupling drops exponentially with distance between redox partners:

$$k_{ET} = \frac{4\pi^2 H_{AB}^2}{h(4\pi\lambda RT)^{1/2}} exp\left[-\frac{(\Delta G^\circ + \lambda)^2}{4\lambda RT}\right] \quad (1)$$

$$k_{ET} = k_0 \, exp[-\beta(r - r_0)] exp\left[-\frac{(\Delta G^\circ + \lambda)^2}{4\lambda RT}\right] \quad (2)$$

where λ is the reorganization energy and ΔG° is the thermodynamic driving force determined from the redox potential difference for the redox partners (FMN and heme in this case). The other parameters have their usual meanings: h is Planck's constant; R is the gas constant; and T is absolute temperature. H_{DA} describes the electronic coupling between electron donor (FMN) and electron acceptor (heme). In Equation (2): $k_0 = 10^{13}$ s^{-1} is the characteristic maximum limit for k_{ET} when donor and acceptor are in van der Waals' contact (i.e. at $r_0 = 3$ Å) and when no activation is involved (i.e. when $\lambda = \Delta G^\circ$). The value of parameter β reflects the nature of the intervening med-

ium in mediating the ET, and a value of 1.4 Å^{-1} is widely used for proteins [36].

In Fig. 2 (lower panel), the heme reduction data as a function of temperature were fit using Equation 1 to obtain estimates of the reorganization energy (λ) and the electronic coupling element (H_{DA}). The ΔG° value used for the fitting was −0.030 eV (or −2.9 kJ·mol^{-1}). This driving force is determined from the difference of midpoint values of the FMN hydroquinone/semiquinone couple and the heme Fe^{III}/Fe^{II}CO couple in nNOS [38,43 46]. Using this ΔG° value, the nonlinear fitting yielded best-fit values for the reorganization energy $\lambda = 139$ kJ·mol^{-1} (or ~ 1.4 eV) and an electronic coupling factor $H_{DA} = 0.2$ cm^{-1}. We have varied ΔG° aiming to investigate whether the values determined by fitting are affected by the driving force used. Changes of as much as ± 60 mV in ΔG° do not result in significant changes in the fitted values of λ or H_{DA}. Fitting the same data to Equation (2) gave a similar value for the reorganization energy $\lambda = 135$ kJ·mol^{-1} (Fig. S2, upper panel), which is not significantly different from $\lambda = 139$ kJ·mol^{-1} determined using Equation (1).

The estimate for H_{DA} in nNOS is within the range known for nonadiabatic ET [35], whereas the estimated reorganization energy ($\lambda = 1.4$ eV) lies on the higher end but is still within the range of reorganizational energies reported for most physiological ET reactions (i.e. $\lambda = 0.5$ 2.3 eV) [36]. The relatively high value of λ in our case reflects a possible coupling of ET to the pre-requisite conformational change needed to bring the FMN domain within a distance required for ET to the heme in the nNOSoxy. Whether an ET reaction is gated or coupled depends on the relative rates of the ET and prerequisite non-ET steps. An estimated value of $K_{eq} = 9.0$ was reported for the FMN FNR domain off/on conformational equilibrium for the reduced, CaM-bound nNOS at 10 °C [38], indicating that, once reduced, the FMN domain is mostly away from the FNR and thus in a conformation that could interact with nNOSoxy for ET. However, the corresponding k_{off} value associated with the FNR FMN equilibrium under this condition is not yet known and, in our experimental design, the FMN domain must first receive electrons from the FNR to become reduced. Also, the K_{eq} for the corresponding FMN NOSoxy equilibrium has been studied in the CaM-bound nNOS poised at different redox states. The data indicate a low value ($K_{eq} \leq 0.2$) [47,48] exists in all cases. This suggests that very little FMN nNOSoxy complex is present at equilibrium and that their interaction is intermittent and/or transient. Given the relatively slow rates for heme reduction that we

observe in nNOS, the relatively high corresponding reorganization energy, and the unfavourable on/off thermodynamic equilibrium for the FMN nNOSoxy interaction, ET from FMN to heme in nNOS is likely coupled to the pre-requisite conformational movement of the FMN domain. Similar ET reactions that are coupled to conformational equilibria are known. One example is the ET reaction from methanol dehydrogenase to the heme in cytochrome *c-551i* where the ET is rate-limiting but still influenced by a pre-requisite rapid but unfavourable conformational arrangement [49].

Our fit of the heme reduction versus temperature data to Equation (2) also yielded an estimate for the distance 'r' (FMN-to-heme distance) (Fig. S2). The estimated distance at the time of the ET event is $r \approx 13.4$ Å. It is important to note that this distance does not change significantly ($r = 13.1$ Å) when the data are fit with Equation (2) using the λ value found in nonlinear fitting with Equation (1) ($\lambda = 139$ kJ·mol^{-1}) (Fig. S2, lower panel). This estimate is in excellent agreement with FMN-to-heme distances of 9 15 Å proposed based on docking models for FMN NOSoxy complexes [40,50]. The value is also consistent with the proposed range (12 13 Å) suggested for nNOS based on the kinetics of heme-to-FMN back ET determined by pulse radiolysis [42] and the recent studies on FMN heme coupling by pulsed EPR for human iNOS [51]. In this case, a distance of 18.8 Å between the FMN-N5 atom and the heme iron was determined, which could correspond to an edge to edge FMN heme distance as short as 13.1 Å [51]. Comparable distances have been reported in related flavocytochrome systems. For example, a value of 18.4 Å has been reported for the FMN to heme iron distance in the complex between the heme and FMN-binding domain of cytochrome P450BM-3 [52].

Temperature dependence of the oxygenation reactions (k_{cat1} and k_{cat2})

The k_{cat1} and k_{cat2} parameters represent the conversion rates of the heme $Fe^{II}O_2$ species to products in the Arg hydroxylation and NOHA oxidation reactions, respectively. We utilized stopped-flow spectroscopy to compare the nNOS heme transitions that occur during the single turnover reactions, as reported in previous studies [53,54]. The reactions were initiated by rapid-mixing an oxygen-containing buffer with pre-reduced ferrous nNOS proteins that contained H_4B and either Arg or NOHA as substrate. For the Arg reactions, we observed two consecutive heme transitions: $Fe^{II} \rightarrow Fe^{II}O_2 \rightarrow Fe^{III}$ and, in the reaction with NOHA, we observed three transitions: $Fe^{II} \rightarrow Fe^{II}O_2 \rightarrow Fe^{III}NO \rightarrow Fe^{III}$. Global analysis of the spectral data according to these models yielded the spectrum of each species (Fig. 3A and 3B, upper panels). The two middle panels of figure 3 show how the concentration of each species changed with time during the reactions. Linear Eyring plots of the observed rates (Fig. 3A and 3B, lower panels) show that both k_{cat1} and k_{cat2} increase as the temperature increases (Table 1) but do so according to significantly different ratios, such that the slope of k_{cat2} is 1.4-fold higher than that of k_{cat1} (Fig. 3A & 3B, lower panels). Fitting the experimental data to the Arrhenius equation yielded an activation energy $E_a = 57.1$ kJ·mol^{-1} for k_{cat1} and 79.5kJ·mol^{-1} for k_{cat2}. Linear Eyring plots give the values for the enthalpy and entropy of activation derived for k_{cat1}: $\Delta H^{\ddagger} = +54.7$ kJ·mol^{-1}; $\Delta S^{\ddagger} = -29$ J·mol^{-1}·K^{-1} (Table 2). The values for the enthalpy and entropy of activation derived for k_{cat2} are: $\Delta H^{\ddagger} = +77$ kJ·mol^{-1}; $\Delta S^{\ddagger} = +56$ J·mol^{-1}·K^{-1} (Table 2). The thermodynamic parameters derived for k_{cat1} are distinguished from k_{cat2} by a negative entropic component. The relative entropic cost observed in the first catalytic step may be attributed to the necessary change in the hydrogen-bonding network expected at the active site upon the transformation of L-arginine to the enzyme bound NOHA [55].

Temperature dependence of NO dissociation (k_d)

A variety of studies [14,25,56,57] indicate that newly-formed NO binds to the NOS ferric heme before it can exit the enzyme. This causes a $Fe^{III}NO$ product complex to form at the end of each catalytic cycle in all NOS enzymes examined to date [19]. In the NOHA single turnover reactions, there was a clear build-up of this immediate $Fe^{III}NO$ product complex (Fig. 3B, upper and middle panels), which allows us to determine the macroscopic off-rate of NO by monitoring its transition to ferric enzyme (k_d parameter in Fig. 1). The macroscopic, observed dissociation rate (k_d) of the $Fe^{III}NO$ product complex is an important parameter because it impacts NOS enzyme distribution during catalysis and, consequently, steady-state NO synthesis activity [19,23,25]. Linear Eyring plots of the observed rates (Fig. 4, upper panel and Table 1) revealed that the k_d parameter has a relatively large temperature dependence, increasing by more than three-fold every 10 °C. The thermodynamic parameters of the reaction were derived from the linear Eyring plot and Arrhenius equation, giving the values: $E_a = 83.1$ kJ·mol^{-1}; $\Delta H^{\ddagger} = 80.7$ kJ·mol^{-1}; $\Delta S^{\ddagger} = 50$ J·mol^{-1}·K^{-1} (Table 2). The activation energy for NO dissociation from Fe^{III}-nNOS (k_d) is quite close to the activation energy for citrulline

formation by nNOS as reported earlier by Iwanaga ($\simeq$103 kJ·mol^{-1}) [58]. Also, the relatively large positive activation entropy that we calculated for the k_d in nNOS is similar to values measured for NO dissociation from other ferric heme proteins such as metmyoglobin ($\Delta H^{\ddagger} = 78$ kJ·mol^{-1}; $\Delta S^{\ddagger} = 46$ J·mol^{-1}·K^{-1}) [59] and the camphor-bound cytochrome P450$_{cam}$ ($\Delta H^{\ddagger} = 84$ kJ·mol^{-1}; $\Delta S^{\ddagger} = 41$ J·mol^{-1}·K^{-1}) [60]. Overall, the process of NO release from ferric heme in nNOS exhibits similar thermodynamic behaviour to that of other heme proteins [59,60] as indicated by comparing Eyring plots for NO release data for the different heme proteins across a range of temperatures (Fig. 4, lower panel). Their similar thermodynamic behaviours are indicative of a common mechanism regulating NO dissociation from the ferric heme and its escape into solution.

What is the basis for the relatively large temperature effect on k_d? Binding and dissociation of diatomic ligands such as NO, CO and O$_2$ to heme proteins is generally accompanied by conformational changes that

sometimes extend far beyond the local heme-binding site [61 63]. This is a consequence of the disparate geometric, electronic and electrostatic requirements imposed by ligand binding and dissociation. The local and global conformational changes and dynamic electrostatic interactions in the binding pocket modulate not only ligand affinities, but also the discrimination between similar diatomic ligands [64,65]. The large temperature dependence of the observed rate of NO dissociation from ferric heme in nNOS and other heme proteins may reflect the control of NO binding at multiple levels. At the heme level, heme distortions have been shown to be critical for stabilizing the Fe^{III}NO complex, particularly in heme proteins whose physiological functions depend on controlling NO release from Fe^{III}-heme [63]. In NOS proteins, the observed out-of-plane modes in the low frequency regions of Raman spectra of the Fe^{III}NO species (oxygenase domain of the inducible nitric oxide synthase and oxygenase domain of the endothelial nitric oxide syn-

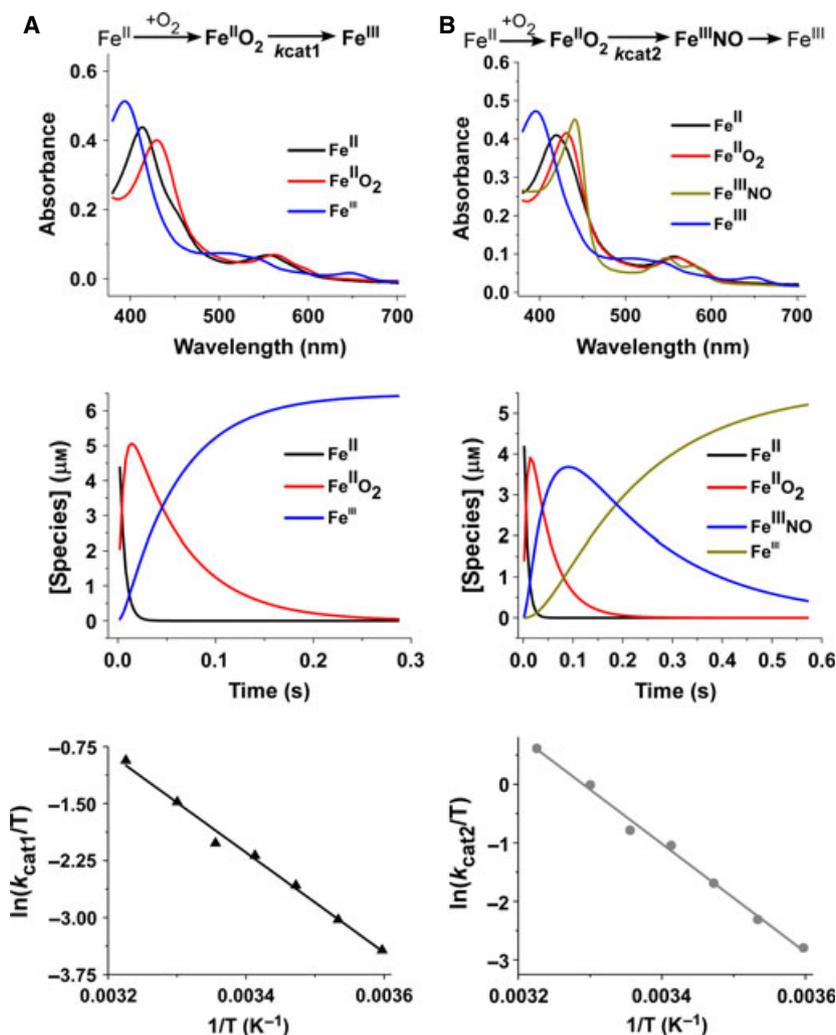

Fig. 3. Temperature dependence of the Arg and NOHA oxidation reactions (A, k_{cat1}; B, k_{cat2}) measured by single catalytic turnover reactions. Lower panel: Eyring plots of the NO release rates of nNOS (present study), metmyoglobin [59] and cytochrome P450cam proteins [60].

thase) have been assigned to heme distortions and have been shown to be critical in increasing d_{xy}-$d\pi$ orbital overlap, which stabilizes the Fe^{III}NO species [62]. At the global protein level, it has been suggested that inter-subunit interactions in the NOS dimer may be important in modulating heme distortion modes [62], which in turn would affect the heme NO dissociation rate k_d. Also, point mutagenesis studies on NOS enzymes identified amino acids near the opening of the heme pocket that help to kinetically gate release of NO [25,66,67]. Thus, the large dependence of k_d on the temperature is likely a result of a general temperature effect on both the heme and protein structural fluctuations and dynamics.

Reaction of O$_2$ with the enzyme Fe^{II}NO complex (k_{ox})

During NO synthesis a portion of the Fe^{III}NO product complex is reduced by the NOS reductase domain and the resulting Fe^{II}NO complex must then react with O$_2$ to return to the catalytic cycle. The rate of this reaction, termed k_{ox}, is a kinetic parameter (Fig. 1) that impacts NOS enzyme distribution during catalysis and, consequently, its steady-state behaviour and NO synthesis activity [19,68–70]. We determined k_{ox} values by mixing anaerobic samples of the nNOSoxy Fe^{II}NO species with an air-saturated solution in the stopped-flow spectrophotometer at 5, 10, 15, 20, 25, 30 and 37 °C and then monitoring the reactions using a diode array detector. Figure 5 (upper panel) shows representative spectral data collected during the reaction of the nNOSoxy Fe^{II}NO complex with air-saturated buffer in the presence of both H$_4$B and L-Arg at 10 °C. The spectral changes are consistent with conversion of the Fe^{II}NO complex into the Fe^{III} high-spin form of nNOSoxy. The reaction was a single-step process with no discernible accumulation of intermediate species, as indicated by the several isosbestic points in the spectra (Fig. 5, upper panel) and by the single-exponential decay of the absorbance signal at two different wavelengths (Fig. 5, upper panel inset), which followed the rate of Fe^{II}NO complex disappearance (436 nm) and the rate of ferric enzyme formation (393 nm). The spectral and fitting results obtained for reactions run at other temperatures were highly similar (data not shown) and the observed k_{ox} rates are listed in Table 1. The corresponding Eyring plot (Fig. 5, lower panel) and Arrhenius equation were used to calculate the thermodynamic parameters: $E_a = 31.9$ kJ·mol^{-1}; $\Delta H^{\ddagger} = 29.4$ kJ·mol^{-1}; $\Delta S^{\ddagger} = -161$ J·mol^{-1}·K^{-1}) (Table 2).

The activation enthalpy for oxidation of the nNOS ferrous heme complex is much lower than the values reported for oxidation of ferrous heme-nitrosyl haemoglobin and myoglobin or for their various mutants ($\Delta H^{\ddagger} = 110$–$120$ kJ·mol^{-1}) [61,71]. Their higher activation enthalpies have been rationalized in terms of a rate-limiting NO dissociation step governing the kinetics of the reversible ligand exchange reaction with O$_2$ that precedes the irreversible oxidation [71]. By contrast, the relatively low $\Delta H^{\ddagger}$ (29.4 kJ·mol^{-1}) that we measured for oxidation of the nNOS ferrous heme-nitrosyl species effectively argues against a NO dissociative mechanism being involved in this case because it is insufficient for breaking the strong heme-Fe^{II}NO bond. The relatively low activation barrier for the nNOS reaction supports our recent mechanistic investigation of nNOS and iNOS heme-nitrosyl oxidation
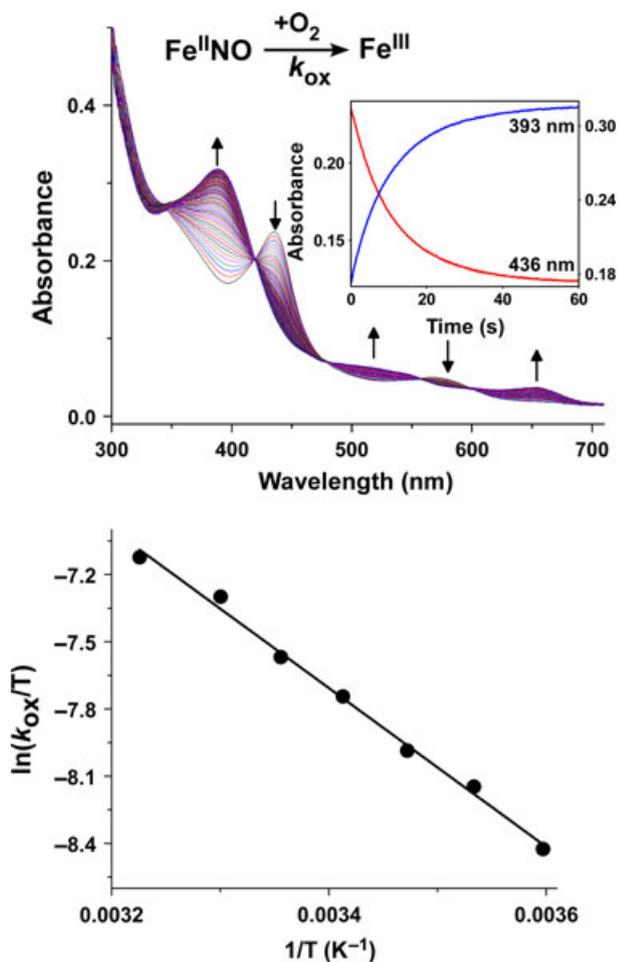

Fig. 5. Temperature dependence of the O_2 reaction with the $Fe^{II}NO$ species (k_{ox}). Anaerobic $Fe^{II}NO$ nNOSoxy was reacted at various temperatures with air saturated buffer in the stopped flow instrument. Upper panel: rapid scanning spectra recorded during a representative reaction, with arrows indicating the direction of the absorbance changes. Inset: absorbance changes versus time at 436 nm ($Fe^{II}NO$ disappearance) and 393 nm (Fe^{III} build up). Lower panel: Eyring plot of the measured k_{ox} values.

reactions, suggesting that it involves a comparatively fast and direct reaction between the ferrous heme-nitrosyl and dioxygen [24].

Steady-state NO synthesis activity

The steady-state NO synthesis activity is a combined reflection of all the individual steps in Fig. 1; thus, its temperature dependence provides apparent thermodynamic parameters for the global process. Table 1 contains NO synthesis activities that we measured across the temperature range for the present study (5 37 °C). The activity increased by approximately 12-fold over this range. The activity data gave a linear Eyring plot

(Fig. 6), from which we determined the activation parameters: $E_a = 54.1$ kJ·mol^{-1}; $\Delta H^{\ddagger} = 51.7$ kJ·mol^{-1}; $\Delta S^{\ddagger} = -74$ J·mol^{-1}·K^{-1} (Table 2). Our E_a value differs somewhat from an earlier study that reported an activation energy of 79.4 kJ·mol^{-1} for the steady-state activity of nNOS, which was derived using measures of citrulline formation from [^{14}C]L-Arg [58].

Implications for nNOS catalytic behaviour

Because the five kinetic parameters investigated in the present study differed with respect to their temperature dependencies, this means that the distribution pattern of nNOS enzyme species during steady-state NO synthesis, and thus nNOS catalytic behaviours, will be temperature-dependent. We utilized the kinetic values that we measured for the five parameters at three different temperatures (10, 25 and 37 °C) in computer simulations of the global kinetic model (Fig. 1) [21] to explore this concept. The model reports on the five main enzyme species that are present during steady-state NO synthesis, namely the ferric, ferrous, ferrous-O_2 (or ferric-superoxy), ferric-NO and ferrous-NO forms (Fig. 1). Any additional kinetic values for associated reactions (i.e. O_2 binding) that we needed for the simulations, besides the five kinetic parameters measured in the present study, are described in the Experimental procedures.

At 10 °C, the simulation showed that the fast k_r relative to the slower k_d and k_{ox} values causes the nNOS

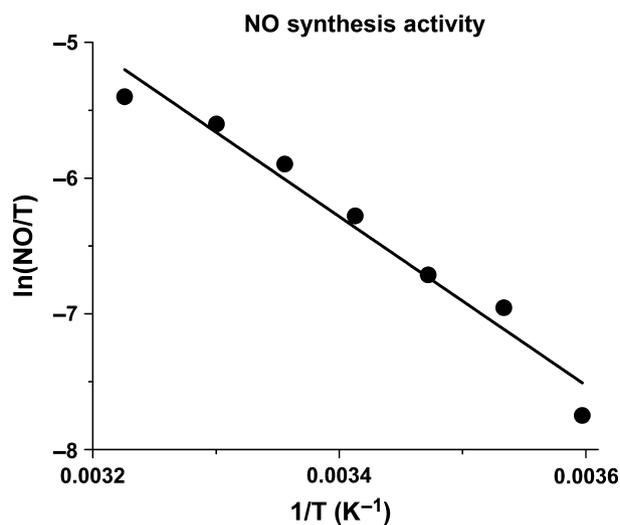

Fig. 6. Eyring plot of nNOS steady state NO synthesis activities recorded at different temperatures. Activities were measured in a conventional spectrophotometer using the oxyhaemoglobin assay for NO as described in the Experimental procedures. On Y axis, NO means Steady state NO synthesis rate.

enzyme to exist predominantly as the $Fe^{II}NO$ species during the steady-state [19,21]. The modelled enzyme distribution indicated that approximately 10% of nNOS is present as ferric enzyme and approximately 86% is present as the $Fe^{II}NO$ species (Fig. 7) at 10 °C, with the remaining 4% of nNOS mainly distributed between the $Fe^{II}O_2$ and $Fe^{III}NO$ species. This falls close to estimates reported in literature [16,19,21,72,73], which range between 67% and 85% $Fe^{II}NO$ complex during steady-state catalysis at 10 °C. However, our experimental data reveal that, at higher temperatures, the rate of $Fe^{III}NO$ dissociation (k_d) increases significantly faster than the k_r and the other kinetic parameters. The simulations indicate how this will alter the steady-state enzyme distributions: At 25 °C, approximately 16% of nNOS is present as ferric enzyme and approximately 81% is present as the $Fe^{II}NO$ species (Fig. 7), with the remaining 3% of nNOS mainly distributed between the $Fe^{II}O_2$ and $Fe^{III}NO$ species, whereas, at 37 °C, which is near the physiological temperature of rats (38 °C) [74,75], only approximately 73% of nNOS is present as the $Fe^{II}NO$ species and approximately 24% is present as ferric enzyme. These simulations clearly show that rat nNOS gains in ferric character and has less $Fe^{II}NO$ complex build-up during NO synthesis as the temperature increases. Overall, the different thermodynamic behaviours of the individual kinetic steps will cause nNOS to become more and more efficient at NO release as the temperature increases, at the same time as diminishing the enzyme cycling into the futile NO dioxygenase pathway (Fig. 1).

A related consequence of the different temperature dependencies is that the relative contributions of the individual kinetic steps toward limiting the NO synthesis activity, and in determining the catalytic behaviours of the enzyme, will change with temperature. For example, at low temperatures (e.g. 10 °C), the k_d and k_r have similar magnitudes. This equivalence diminishes the release of NO as a result of approximately half of the $Fe^{III}NO$ product complex being diverted into the futile cycle. Consequently, this increases the impact of k_{ox} on the observed enzyme NO synthesis activity and on its apparent oxygen concentration dependence (i.e. apparent K_mO_2). Specifically, NO synthesis activity becomes much more dependent on the oxygen concentration relationship of the NO dioxygenase reaction described by k_{ox} [72], which displays a linear relationship with O_2 concentration across the entire physiological range [24]. However, at higher temperatures, the k_d becomes increasingly faster than the k_r, which enables a quicker and greater release of NO from the $Fe^{III}NO$ product complex, consequently diminishing enzyme partitioning into the futile cycle. This in turn diminishes the role of k_{ox} in limiting the overall NO synthesis activity and diminishes its role in determining the apparent K_mO_2 for NO synthesis activity, such that the apparent K_mO_2 becomes more reflective of the oxygen concentration dependence of the biosynthetic reactions, which depend on the ferrous heme affinity for O_2 binding. Thus, at higher temperatures (i.e. 37 °C) the contribution of k_r in determining the overall NO synthesis activity is increased, whereas the contribution of k_{ox} is diminished, with accompanying changes in nNOS enzyme behaviour and the O_2 concentration response.

Experimental procedures

General methods and materials

All reagents and materials were obtained from Sigma Aldrich (St Louis, MO, USA), Amersham Biosciences

	10 °C	25 °C	37 °C
Fe^{III}	9.6 %	15.6 %	23.9 %
Fe^{II}	0.3 %	0.1 %	0.0 %
$Fe^{II}O_2$	1.8 %	1.5 %	1.4 %
$Fe^{III}NO$	2.0 %	1.9 %	1.7 %
$Fe^{II}NO$	86.2 %	80.9 %	72.9 %
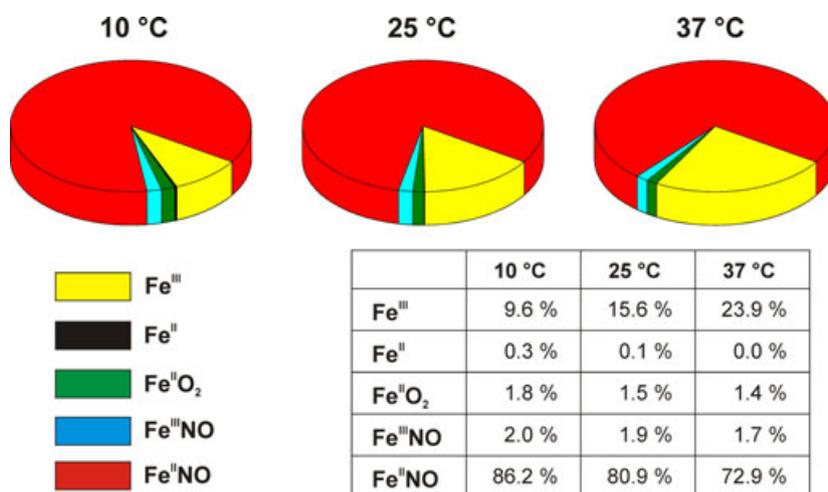

Fig. 7. Temperature effect on the distribution of the five principal enzyme species during steady state NO synthesis by nNOS. Distributions were calculated by a computer simulating a global kinetic model similar to the one shown in Fig. 1. Rate constants used for the calculations are given in Table 3. Steady state values were determined after 50 s of simulated reaction, although a steady state distribution is reached within 5 10 s in all cases.

(Little Chalfont, UK) or other sources, as described previously [20,70,76]. Absorption spectra and steady state kinetic data were obtained using a Shimadzu UV 2401PC spectro photometer (Shimadzu Corp., Kyoto, Japan). Stopped flow experiments were performed using a Hi Tech Scientific KinetAsyst SF 61DX2 stopped flow system (Hi Tech Scientific, Salisbury, UK) equipped with an anaerobic set up and a rapid scanning photodiode array detector. Data from multiple identical stopped flow experiments were averaged to improve the signal to noise ratio. We did not find much difference in values when individual rates were averaged or the rate was calculated from averaged trace. We calculated SD values from the individual observed rates. The spectral traces were fit according to single or multiple exponential equations using software provided by the manufacturer. The best fit was determined when adding further exponentials did not produce a significant improvement of the fit as judged from the residuals. All plots and some additional curve fitting were performed using ORIGIN, version 8.0 (OriginLab, Northampton, MA, USA). Anaerobic samples were prepared in an air tight cuvette using repeated cycles of vacuum followed by a positive pressure of catalyst deoxygenated nitrogen gas.

Expression and purification of wild-type protein

All proteins were purified in the presence of H_4B and L Arg as described previously [20,26,70,76]. The ferrous heme CO adduct absorbing at 444 nm was used to measure heme protein content with an extinction coefficient of $\varepsilon_{444} = 74$ $mM^{-1}\cdot cm^{-1}$ (A_{444} A_{500}) [76]. The purity of each protein was assessed by SDS/PAGE and spectral analysis.

NO synthesis measurement

Steady state NO synthesis was determined at 5, 10, 15, 20, 25, 30 and 37 °C using the spectrophotometric oxyhaemoglobin assay, as described previously [76].

Anaerobic heme reduction measurements

The kinetics of heme reduction were analyzed at 5, 10, 15, 20, 25, 30 and 37 °C, as described previously [20,26,70,76,77], using a stopped flow apparatus and diode array detector (Hi Tech Scientific KinetAsyst SF 61DX2) equipped for anaerobic analysis.

Reaction of $Fe^{II}NO$ complexes with oxygen

The kinetics of $Fe^{II}NO$ oxidation were analyzed at 5, 10, 15, 20, 25, 30 and 37 °C, as described previously [24,70], using a stopped flow apparatus and diode array detector (Hi Tech Scientific KinetAsyst SF 61DX2) equipped for anaerobic analysis.

Single turnover reactions

Arginine hydroxylation experiments were carried out in a Hi Tech SF61 DX2 stopped flow instrument coupled to a diode array detector, as described previously [14]. The reactions were studied at 5, 10, 15, 20, 25, 30 and 37 °C in the presence of 50 μM H_4B, 2.5 mM L arginine, 150 mM NaCl, 10% glycerol, 1 mM dihiothreitol in 40 mM Epps buffer (pH 7.6). nNOSoxy at a concentration of 10 μM was titrated with sodium dithionite and mixed with air saturated buffer at the respective temperatures ([O_2] = ~ 360 μM, 270 μM and 215 μM at 10, 25 and 37 °C, respectively). NOHA oxidation was studied in the same conditions replacing L arginine by 1 mM NOHA. Sequential spectral data were fitted to A→ B→ C (Arg hydroxylation; Fe^{II}→ $Fe^{II}O_2$→Fe^{III}) and A→ B→ C→ D (NOHA oxidation; Fe^{II}→ $Fe^{II}O_2$→$Fe^{III}NO$→Fe^{III}) kinetic models using SPECFIT/32 global analysis software, version 3.0 (Spectrum Software Associates, Marlborough, MA, USA) to obtain the spectra of the different species and the reaction rates. Using SPECFIT/32, we calculated rates for k_{cat1} (during Arg hydroxylation) and k_{cat2} (during NOHA oxidation).

Temperature-dependence and thermodynamic analysis

The natural log of the observed rates or rate constants for each averaged set of experimental data were plotted against the reciprocal of the absolute temperature. To calculate the activation energy, the data were then fit to the Arrhenius equation (Equation 3) using the linear fitting function in ORIGIN. In Equation (3), A is the Arrhenius pre exponential factor and R is the gas constant and E_a is activation energy. Activation enthalpy ($\Delta H^{\ddagger}$) and activation entropy ($\Delta S^{\ddagger}$) were calculated on the basis of Eyring equation (Equation 4) and Eyring plot [ln(k/T) versus $1/T$]. Because the Gibbs free energy of activation ($\Delta G^{\ddagger}$) depends on temperature, it can be calculated for each step at a given temperature and we calculated $\Delta G^{\ddagger}$ at 25 °C using the Equation (5), whereas, $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ are virtually independent of temperature:

$$lnk \quad lnA \quad E_a/RT \tag{3}$$

$$ln(k/T) \quad \Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R + ln(k_B/h) \tag{4}$$

$$\Delta G^{\ddagger} \quad RT[ln(k_BT/h) \quad lnk] \tag{5}$$

where k is the reaction rate constant; T is the absolute temperature; R is the gas constant (8.314472 J mol^{-1}·K^{-1}); k_B is the Boltzmann constant ($1.3806504 \times 10^{-23}$ J·K^{-1}); h is Planck's constant (6.626×10^{-34} J·s^{-1}); $\Delta H^{\ddagger}$ is the enthalpy of activation; $\Delta S^{\ddagger}$ is the entropy of activation; $\Delta G^{\ddagger}$ is the Gibbs free energy of activation; and E_a is the energy of activation.

Table 3. Calculated rates used for the computer simulations. (a) ʟ Arg bound enzyme; (b) NOHA bound enzyme; (b*) ferric enzyme with NOHA and H_4B radical bound; for details, see Fig. 1 and Fig. S1. All values are in s^{-1}. For bimolecular reactions (k_2, k_6, k_{10}), the value used in the calculations is the product of the 'actual' value and the concentration of oxygen, which is considered to remain constant during the reaction. For k_2 and k_6, the values used are the experimental values multiplied by 2 (assumes the rate is proportional to $[O_2]$, experimental values are determined in half air saturated conditions). For k_{10}, the values used are the experimentally determined values $\times$ 1.5, as based on the observed oxygen dependence reported in Tejero et al. [24]. k_{11} values are interpolated from Salerno [17].

			Temperature						
			5 °C	10 °C	15 °C	20 °C	25 °C	30 °C	37 °C

Simulations of nNOS distribution during steady-state NO synthesis

The NO synthesis kinetics were simulated using the glo bal model as implemented in MATHCAD, version 7.0 [18,21] or GEPASI, version 3.30 [78]. Slight changes in the model were introduced to account for the pterin reduc tion step, as shown in Fig. 1. Both methods yielded simi lar results. Simulations assume constant values for $[O_2] = \sim 360$ μM, 270 μM and 215 μM at 10, 25 and 37 °C, respectively, and [NADPH] = 40 μM. This approxi mation allows to treat all the processes as unimolecular reactions and assimilate the observed rates to apparent rate constants. Thus, for bimolecular reactions k_2, k_6 and k_{10} (Table 3), the observed rate is the product of the real rate constant multiplied by the concentration of oxygen. We base our simulations on the observed rates using a correction factor to estimate the value in air saturated buffer instead of the half air saturated experimental con ditions. Experimentally observed oxidation rates (k_{ox}), which we derived at half air saturated condition, were multiplied by a factor of 1.5 to approximate a full air saturated condition according to the dependence observed previously [24]. We also multiplied the observed oxygen binding rate k_2 and k_6 values by a factor of 2.0 to obtain a full air saturated condition assuming that the rate is proportional to $[O_2]$. The values for heme reduction (k_r), NO dissociation (k_d), $Fe^{II}NO$ oxidation (k_{ox}) and all other rates at different temperatures are shown in Table 3. The percentage of species in the steady state is calculated after 50 s of simulation, although a steady state distribution is reached within 5 10 s in all cases.
